

Design of Wind Energy Systems

Tutorial 4: Load Calculation and Design

Fig. www.windaction.org

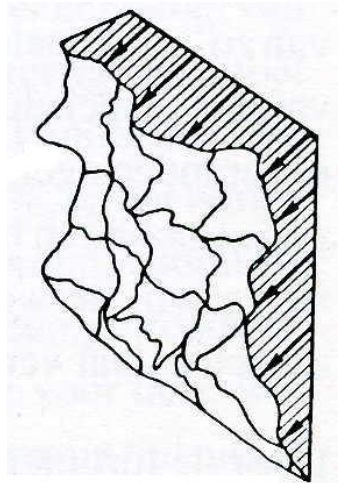

Exercise 1:

- Definition of possible critical events to consider in the load calculation

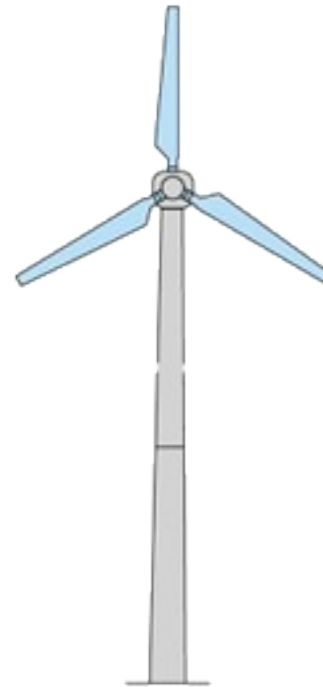

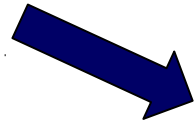

Exercise 2:

- Definition of the number of cycles in a time series using the “rain flow” approach

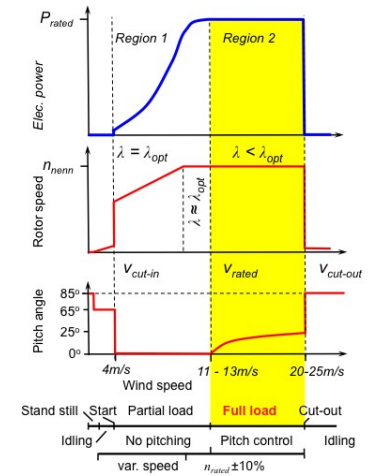

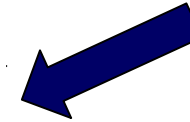

Origin of design load cases

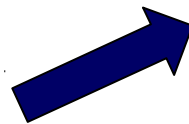

Wind

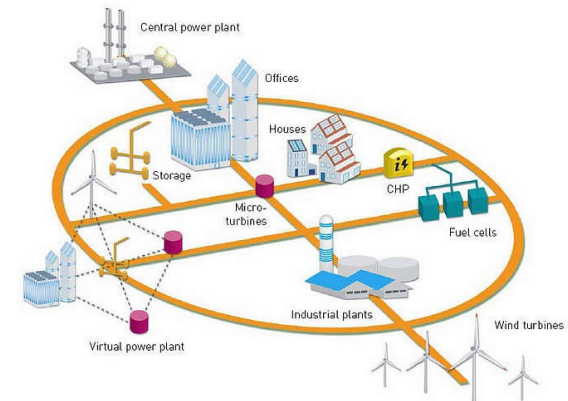

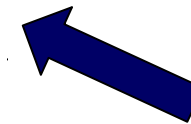

Control System

External Environment

Grid

Failures

Assignment 1

Please fill the following table with the events or operations you think you should consider in the load calculation e.g. for wind speed/direction. Add also the relative consequences and the wind turbine component that would be most affected.

	Event/Operation	Consequence
Wind		
WT System		
Environment		

Assignment 1: solution

Please fill the following table with the events or operations you think you should consider in the load calculation e.g. for wind speed/direction. Add also the relative consequences and the wind turbine component that would be most affected.

	Event/Operation	Consequence
Wind	<ul style="list-style-type: none"> •Gusts •Extreme change in the wind direction •Extreme/normal wind speed •Extreme/normal turbulence intensity •Partial/full wake •Normal/extreme shear 	<ul style="list-style-type: none"> •Pitch control action •Yawed inflow •Different loading condition •Different fatigue cycles •Non-symmetric loads on the swept area
WT System	<ul style="list-style-type: none"> •Start/stop •Idling •Yaw control one blade pitch failure •Pitch control failure •Emergency stop •Power production 	<ul style="list-style-type: none"> •Inertial loads •Non-symmetric loads on the swept area •Over-speed •High inertial loads, increase of temperature in the nacelle •Operational loads
Environment	<ul style="list-style-type: none"> •Earthquake •Extreme/normal waves •Grid failure •Lightening •Transport/Assembling •Icing •Salty atmosphere 	<ul style="list-style-type: none"> •Over-speed •Thermal stresses

Fatigue (I)

Ultimate loads are not enough to ensure the reliability of a component.

Loads much lower than the design loads may cause the collapse of a component when cyclically repeated a certain amount of times.

Microscopically small defects in components after **cyclic loading** may deteriorate to cracks which slowly grow until they lead to the **fatigue failure** of component.

Evaluation of the number of cycles per year:

- For each wind speed interval I_p a ten minutes series of the stresses relative to most loaded sections is recorded.
- Stress cycles are counted according to the cycle mean amplitude σ_{mi} and range σ_{rj} (note: sometimes only the range is taken into account)
- The number count of the same stress cycle $\sigma_{mi,rj}$ found for different wind conditions are added together
- From the probability density function of the wind speed the number of cycles per year $n_{i,j}$ is estimated
- Stress cycles from operational loads are added to $n_{i,j}$ (e.g. start, stop)

Fatigue (II)

Evaluation of the material lifetime from the Palmgren-Miner rule:

The **damage D** evaluated from the sum of the stress cycles $n_{\text{tot},ij}$ given in the lifetime T , normalized with the number of cycles N_{ij} leading to failure for cyclic loading with the stresses σ_{mi} and range σ_{rj} found in the S-N curve or Wöhler curve of the considered material, has to be **lower than 1**.

$$D = \sum_{i,j} \frac{n_{\text{tot}}(\sigma_{mi}, \sigma_{rj})}{N_{ij}} = \sum_{i,j} \frac{T \cdot n_{ij}}{N_{ij}} < 1$$

By inverting the above equation it is possible to evaluate the lifetime T of the material:

$$T = \frac{1}{\sum_{i,j} \frac{n_{ij}}{N_{ij}}}$$

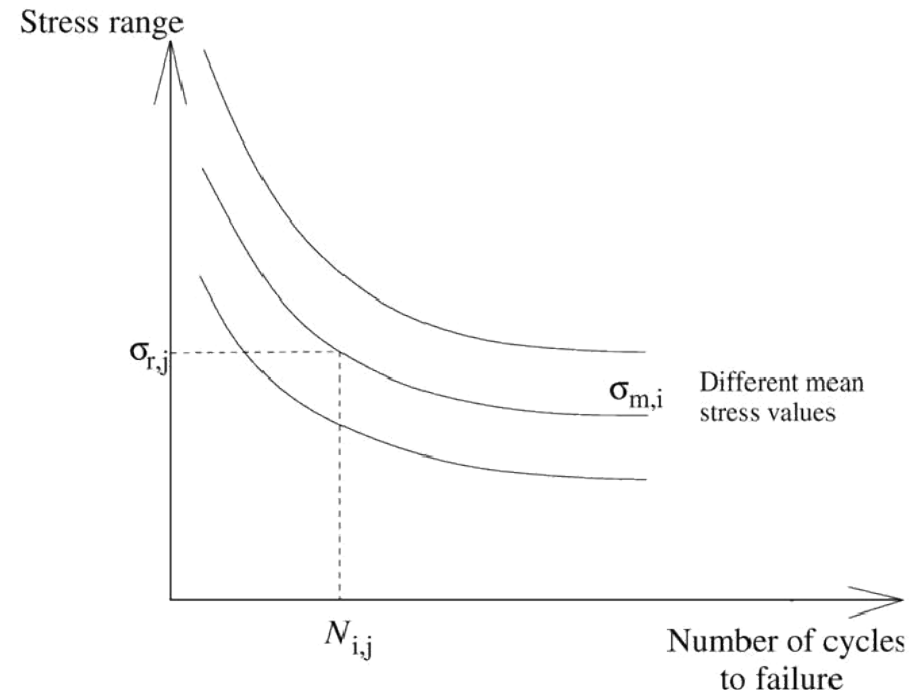

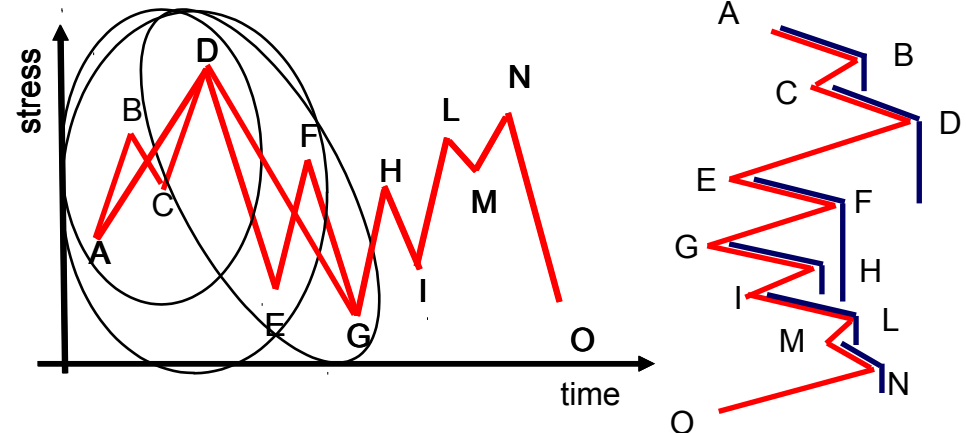

Fig. Hansen 2008

Rain-flow count method

Counts the stress cycles imaging that the peaks as well as the troughs of a time series rotated by 90 degree define the surface line of a pagoda roof where the rain is dropping from. Half cycles are counted when:

- a rain flow from a peak (trough) reaches the end of the time history or an other peak (trough)
- the considered peak (trough) is followed by a trough (peak) at least of the same amplitude

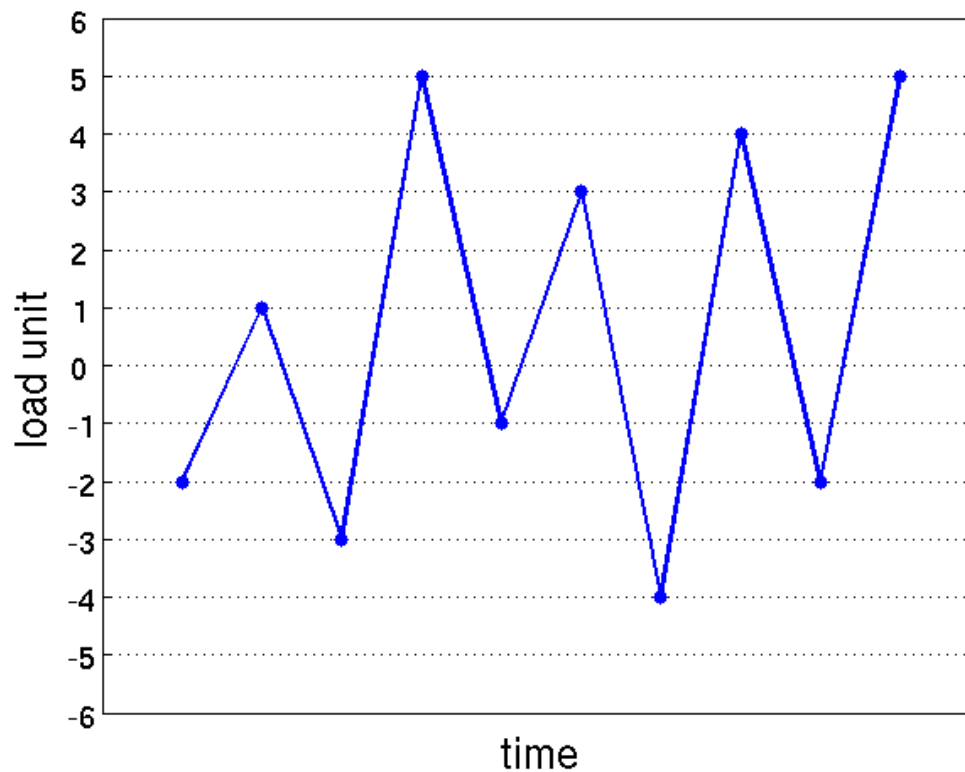

Algorithms

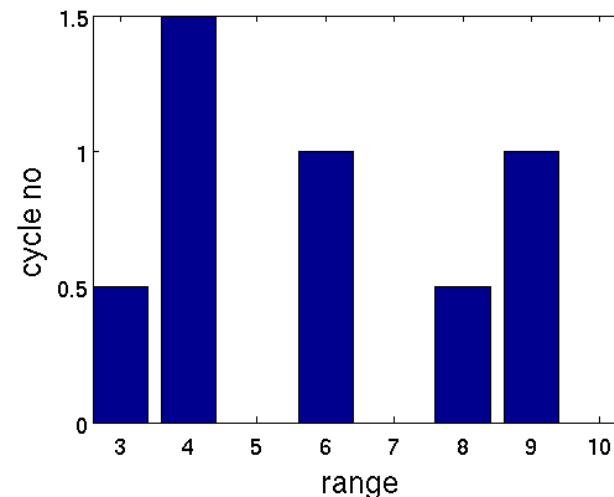

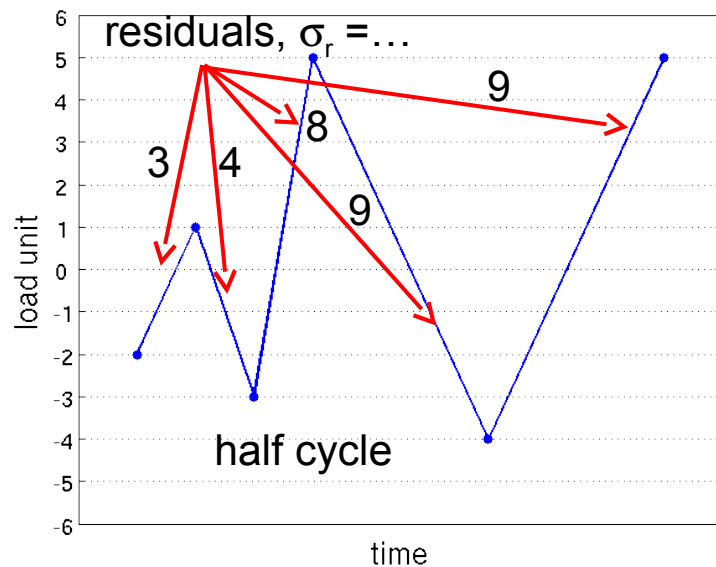

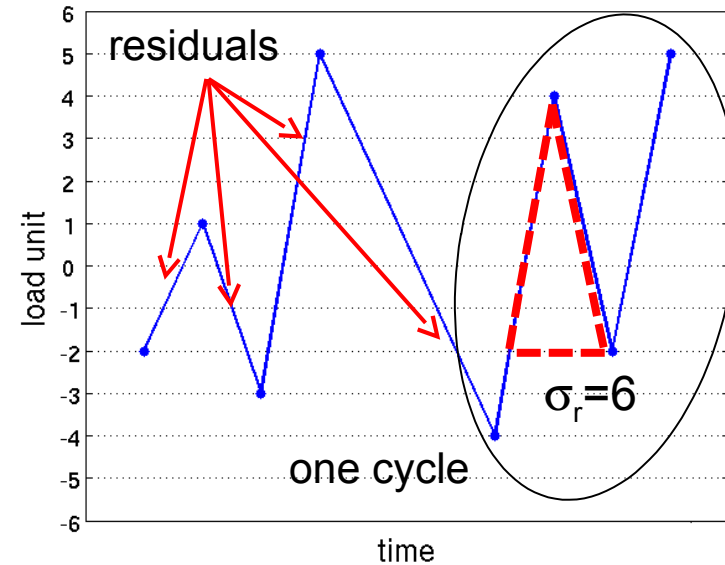

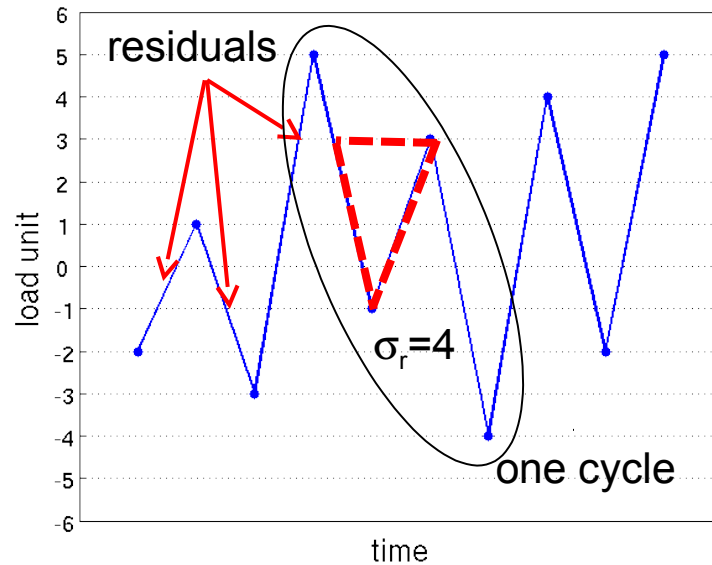

1. Reduce the time series to peaks and troughs
2. Consider the first group of 4 data $S_i, S_{i+1}, S_{i+2}, S_{i+3}$
3. The pair range $|S_{i+1} - S_{i+2}|$ is counted as cycle and the relative data dismissed if the pair is totally included in within S_i and S_{i+3} otherwise the index i is increased by 1 (repeat till possible)
4. The remaining ranges are considered individually as half cycles

Assignment 2

For the given data series defines the occurring range cycles and count their frequency according to the rain-flow method.

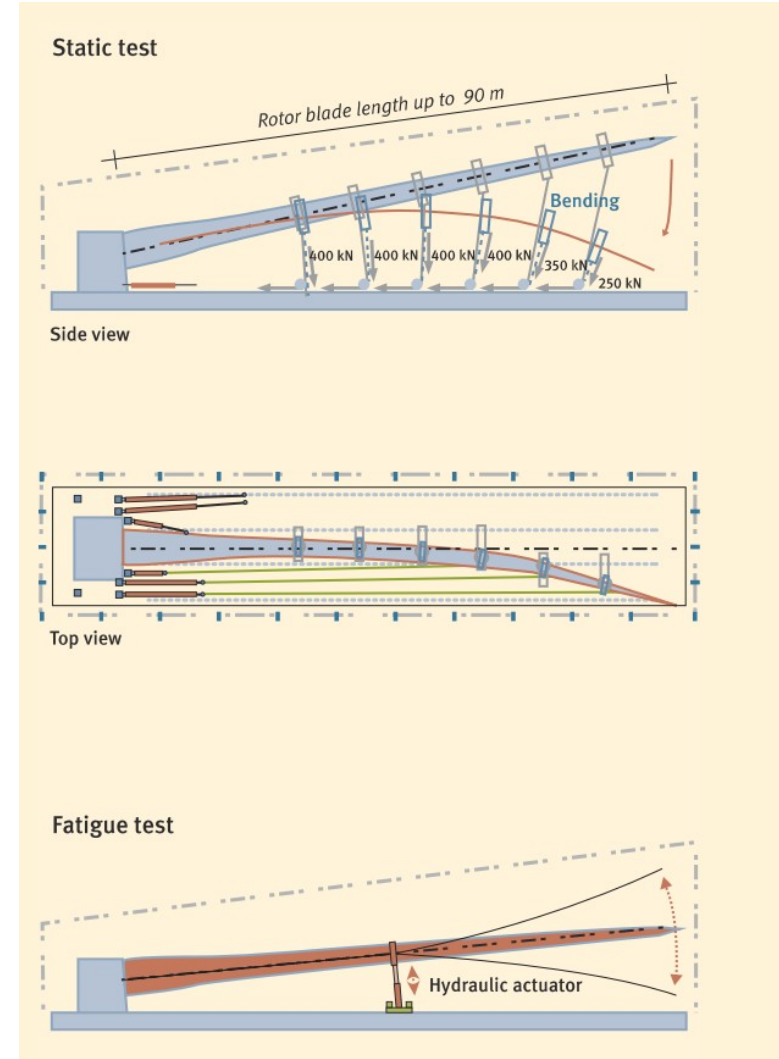

Assignment 2: solution

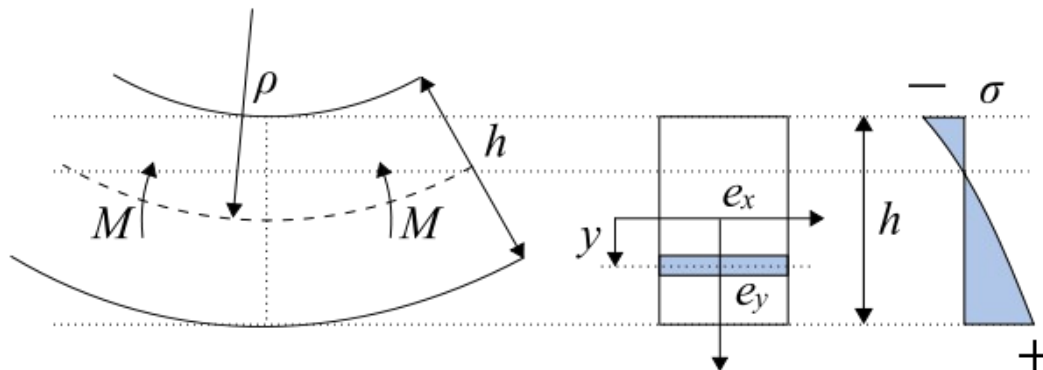

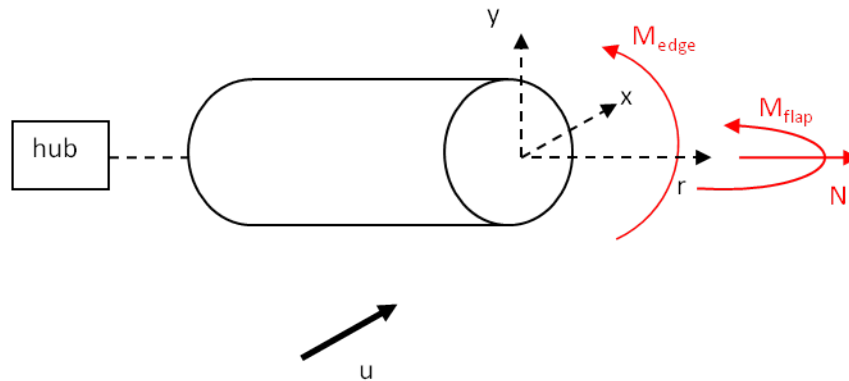

Structural test on blades

Excitation at the structure at the eigenfrequency of the blade

Home assignment

- De Saint Venant beam model
- Sections do not deform while bending
- Main inertial axis
